Abstract

This paper considers the application of integral Linear Quadratic Gaussian (LQG) optimal control theory to a problem of cavity locking in quantum optics. The cavity locking problem involves controlling the error between the laser frequency and the resonant frequency of the cavity. A model for the cavity system, which comprises a piezo-electric actuator and an optical cavity is experimentally determined using a subspace identification method. An LQG controller which includes integral action is synthesized to stabilize the frequency of the cavity to the laser frequency and to reject low frequency noise. The controller is successfully implemented in the laboratory using a dSpace DSP board.

I. INTRODUCTION

Many future technologies will be based on quantum systems manipulated to achieve engineering outcomes [1, 2]. Quantum feedback control forms one of the key design methodologies that will be required to achieve these quantum engineering objectives [3, 4, 5, 6, 7, 8, 9, 10]. Examples of quantum systems in which quantum control may play a key role include the quantum error correction problem (see [11]) which is central to the development of a quantum computer and also important in the problem of developing a repeater for quantum cryptography systems, spin control in coherent magnetometry (see [12]), control of an atom trapped in a cavity (see [8]), the control of a laser optical quantum system (see [13]), control of atom lasers and Bose Einstein Condensates (see [14]), and the feedback cooling of a nanomechanical resonator (see [15]).

Attention is now turning to more general aspects of quantum control, particularly in the development of systematic quantum control theories for quantum systems. For example in [8] and [16] it was shown that the linear quadratic Gaussian (LQG) optimal control approach to controller design can be extended to linear quantum systems. Also, in [17], it was shown that the H^∞ optimal control approach to controller design can be extended to linear quantum systems. These theoretical results indicate that systematic optimal control methods of modern control theory have the potential of being applied to quantum systems. Such modern control theory methods have the advantage that they are strongly model based and provide systematic methods of designing multivariable control systems which can achieve excellent closed loop performance and robustness. Experimental demonstrations of some of these theoretical results now appear viable. For example, Ref. [18] presents the first experimental demonstration of the design and implementation of a “coherent controller” from within this formalism.

One particular systematic approach to control is the LQG optimal control approach to design. LQG optimal control is based on a linear dynamical model of the plant being controlled which is subject to Gaussian white noise disturbances; e.g, see [19]. In LQG optimal control, a dynamic linear output feedback controller is sought to minimize a quadratic cost functional which encapsulates the performance requirements of the control system. A feature of the LQG optimal control problem is that its solution involves the use of a Kalman Filter which provides estimates of the internal system variables. Furthermore, in many ap-

plications integral action is required in order to overcome low frequency disturbances acting on the system being controlled. This issue is addressed here by using a version of LQG optimal control referred to as integral LQG control which forces the controller to include integral action; see [20].

In this paper, we consider the application of systematic methods of LQG optimal control to the archetypal quantum optical problem of locking the resonant frequency of an optical cavity to that of a laser. Homodyne detection of the reflected port of a Fabry-Perot cavity is used as the measurement signal for an integral LQG controller. In our case, the linear dynamic model used is obtained using both physical considerations and experimentally measured frequency response data which is fitted to a linear dynamic model using subspace system identification methods; e.g., see [21]. The integral LQG controller design is discretized and implemented on a dSpace digital signal processing (DSP) system in the laboratory and experimental results were obtained showing that the controller has been effective in locking the optical cavity to the laser frequency. We also compare the step response obtained experimentally with the step response predicted using the identified model.

This paper is structured as follows: In Section II the quantum optical model of an empty cavity is formulated in a manner consistent with the LQG design methodology; Section III outlines the subspace system identification technique used to arrive at the linear dynamic model for the cavity system; Section IV presents the LQG optimal controller design methodology as applied to the problem of locking the frequencies of a laser and of an empty cavity together; Section V presents experimental results; and we conclude in Section VI.

II. CAVITY MODEL

A schematic of the frequency stabilization system is depicted in Fig. 1.

The cavity can be described in the Heisenberg picture by the following quantum stochastic differential equations; e.g., see [22] and Section 9.2.4 of [23]:

$$\begin{aligned}\dot{a} &= -\left(\frac{\kappa}{2} + i\Delta\right)a - \sqrt{\kappa_0}(\beta + b_0) \\ &\quad - \sqrt{\kappa_1}b_1 - \sqrt{\kappa_L}b_L; \\ b_{out} &= \sqrt{\kappa_0}a + \beta + b_0.\end{aligned}\tag{1}$$

Here, the annihilation operator for the cavity mode is denoted by a and the annihilation

FIG. 1: Cavity locking feedback control loop.

operator for the coherent input mode is denoted by $b = \beta + b_0$, both defined in an appropriate rotating reference frame. Here b_0 is quantum noise. We have written $\kappa = \kappa_0 + \kappa_1 + \kappa_L$, where κ_0 , κ_1 and κ_L quantify the strength of the couplings of the respective optical fields to the cavity, including the losses. The input to the cavity is taken to be a coherent state with amplitude β and which is assumed to be real without loss of generality. Δ denotes the frequency detuning between the laser frequency and the resonant frequency of the cavity. The objective of the frequency stabilization scheme is to maintain $\Delta = 0$. The detuning is given by [24]

$$\Delta = \omega_c - \omega_L = q \frac{2\pi c}{nL} - \omega_L, \quad (2)$$

where ω_c is the resonant frequency of the cavity, ω_L is the laser frequency, nL is the optical path length of the cavity, c is the speed of light in a vacuum and q is a large integer indicating that the q^{th} longitudinal cavity mode is being excited.

The cavity locking problem is formally a nonlinear control problem since the equations governing the cavity dynamics in (1) contain the nonlinear product term Δa . In order to apply linear optimal control techniques, we linearize these equations about the zero-detuning point. Let α denote the steady state average of a when $\Delta = 0$ such that $a = \alpha + \tilde{a}$. The perturbation operator $\tilde{a}$ satisfies the linear quantum stochastic differential equation (neglecting higher order terms)

$$\dot{\tilde{a}} = -\frac{\kappa}{2}\tilde{a} - i\Delta\alpha - \sqrt{\kappa_0}b_0 - \sqrt{\kappa_1}b_1 - \sqrt{\kappa_L}b_L. \quad (3)$$

The perturbed output field operator $\tilde{b}_{out}$ is given by

$$\tilde{b}_{out} = \sqrt{\kappa_0}\tilde{a} + b_0 \quad (4)$$

which implies $b_{out} = \sqrt{\kappa_0}\alpha + \beta + \tilde{b}_{out}$.

We model the measurement of the X_ϕ quadrature of $\tilde{b}_{out}$ with homodyne detection by changing the coupling operator for the laser mode to $\sqrt{\kappa_0}e^{-i\phi}a$, and measuring the real quadrature of the resulting field. The measurement signal is then given by

$$\tilde{y} = \tilde{b}_{out} + \tilde{b}_{out}^\dagger = \sqrt{\kappa_0}(e^{-i\phi}\tilde{a} + e^{i\phi}\tilde{a}^\dagger) + q_0 \quad (5)$$

where $q_0 = b_0 + b_0^\dagger$ is the intensity noise of the input coherent state.

As we shall see in Section IV, the LQG controller design process starts from a state-space model of the plant, actuator and measurement, traditionally expressed in the form:

$$\begin{aligned} \dot{x} &= Ax + Bu + D_1w; \\ y &= Cx + D_2w \end{aligned} \quad (6)$$

where x represents the vector of system variables (we shall not use the control engineering term “states” to avoid confusion with quantum mechanical states), u is the input to the system, y is the measured output, and w is a Gaussian white noise disturbance acting on the system. Also, A represents the system matrix, B is the input matrix, C is the output matrix, and D_1 and D_2 are the system noise matrices.

The cavity dynamics and homodyne measurement are expressed in state-space form in

terms of the quadratures of the operators $\tilde{a}, b_0, b_1, b_L$ as

$$\begin{aligned}
\begin{bmatrix} \dot{\tilde{q}} \\ \dot{\tilde{p}} \end{bmatrix} &= \begin{bmatrix} -\frac{\kappa}{2} & 0 \\ 0 & -\frac{\kappa}{2} \end{bmatrix} \begin{bmatrix} \tilde{q} \\ \tilde{p} \end{bmatrix} + \begin{bmatrix} 0 \\ 2\alpha \end{bmatrix} \Delta \\
&\quad - \sqrt{\kappa_0} \begin{bmatrix} \cos \phi & -\sin \phi \\ \sin \phi & \cos \phi \end{bmatrix} \begin{bmatrix} q_0 \\ p_0 \end{bmatrix} \\
&\quad - \sqrt{\kappa_1} \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix} \begin{bmatrix} q_1 \\ p_1 \end{bmatrix} \\
&\quad - \sqrt{\kappa_L} \begin{bmatrix} 1 & 0 \\ 0 & 1 \end{bmatrix} \begin{bmatrix} q_L \\ p_L \end{bmatrix} ; \\
y &= k_2 \sqrt{\kappa_0} \begin{bmatrix} \cos \phi & \sin \phi \end{bmatrix} \begin{bmatrix} \tilde{q} \\ \tilde{p} \end{bmatrix} \\
&\quad + k_2 \begin{bmatrix} 1 & 0 \end{bmatrix} \begin{bmatrix} q_0 \\ p_0 \end{bmatrix} + w_2 \\
&= z + k_2 \begin{bmatrix} 1 & 0 \end{bmatrix} \begin{bmatrix} q_0 \\ p_0 \end{bmatrix} + w_2
\end{aligned} \tag{7}$$

with noise quadratures $q_j = b_j + b_j^\dagger$, $p_j = -i(q_j - p_j^\dagger)$, for $j = 0, 1, L$ (all standard Gaussian white noises). Here, y is the homodyne detector output in which we have included an electronic noise term w_2 . Also, k_2 represents the transimpedance gain of the homodyne detector, including the photodetector quantum efficiency.

III. SUBSPACE SYSTEM IDENTIFICATION

The state-space model of the cavity given in (7) is incomplete as it does not include an explicit model, including the actuation mechanism, for the dynamics of the detuning, Δ . The dynamics of the detuning and actuation mechanism are sufficiently complex that direct measurement is a more experimentally reasonable approach than *a priori* modeling of the system. Following these measurements, an approach called subspace system identification is used to obtain the complete state-space model.

It is at this point that the controller design process diverges from traditional, pre-1960s control techniques. Specifically, in the traditional approach, a controller is designed using

root-locus or frequency response methods, based on measurements of the plant transfer function [25]. In our modern control approach, the subspace identification method determines a state-space model from the input-output frequency response data and generates the system matrices A , B and C in (6); see [26]. The system matrices are used in the LQG design process as we shall see in Section IV.

The transfer function of the cavity and measurement system (or alternatively the “plant”) is identified under closed-loop conditions. We use an analog proportional-integral (PI) controller to stabilize the system for the duration of the measurement. The frequency response data thus obtained for the plant is plotted in Fig. 2. From the data, at least three resonances can be clearly identified, occurring at frequencies of about 520, 2100 and 5000 Hz respectively.

FIG. 2: Measured plant frequency response.

An 8th-order anti-aliasing filter with a corner frequency of 2.5 kHz (chosen because it is far greater than the unity-gain bandwidth of the controller and far less than the 50 kHz sampling frequency) was placed immediately prior to the digital LQG controller. This is treated mathematically as augmenting the plant such that the augmented plant has a frequency response that is the product of the plant data gathered previously and the anti-aliasing filter which is identified separately.

The frequency response data obtained is then fitted to a 13th order model using a subspace identification method; see [21]. The algorithm accommodates arbitrary frequency spacing

and is known to provide good results with flexible structures. This makes it suitable for our application which includes a piezo-electric actuator coupled to the cavity mirror. Fig. 3 compares the gain (in dB) and the phase (in deg) of the measured frequency data for the augmented plant with that of its identified system model.

FIG. 3: Measured frequency response data for the augmented plant and frequency response for the identified system model.

IV. LINEAR QUADRATIC GAUSSIAN OPTIMAL CONTROL

The LQG optimal control approach to controller design begins with a linear state-space model of the form (6). Note that this model involves the use of Gaussian white noise disturbances although a more rigorous formulation of the LQG optimal control problem involves the use of a Wiener process to describe the noise rather than the white noise model (6); e.g., see [27]. However, for the purposes of this paper, a model of the form (6) is most convenient. In the model (6), the term D_1w corresponds to the process noise and the term D_2w corresponds to the measurement noise. The LQG optimal control problem involves constructing a dynamic measurement feedback controller to minimize a quadratic cost functional of the form

$$\mathcal{J} = \lim_{T \rightarrow \infty} \mathbf{E} \left[\frac{1}{T} \int_0^T [x^T Q x + u^T R u] dt \right] \quad (8)$$

where $Q \geq 0$ and $R > 0$ are symmetric weighting matrices. The term $x^T Q x$ in the cost functional (8) corresponds to a requirement to minimize the system variables of interest and the term $u^T R u$ corresponds to a requirement to minimize the size of the control inputs. The matrices Q and R are chosen so that the cost functional reflects the desired performance objectives of the control system. The great advantage of the LQG optimal control approach to controller design is that it provides a tractable systematic way to construct output feedback controllers (even in the case of multi-input multi-output control systems). Also, numerical solutions exist in terms of algebraic Riccati equations which can be solved using standard software packages such as Matlab; e.g., see [19, 28]. A feature of the solution to the LQG optimal control problem is that it involves a Kalman filter which provides an optimal estimate $\hat{x}$ of the vector of system variables x based on the measured output y . This is combined with a “state-feedback” optimal control law which is obtained by minimizing the cost functional (8) as if the vector of system variables x was available to the controller.

Note that the LQG controller design methodology cannot directly handle some important engineering issues in control system design such as robustness margins and controller bandwidth. These issues can however be taken into account in the controller design process by adding extra noise terms to the plant model (over and above the noise that is present in the physical system) and by suitably choosing the quadratic cost functional (8).

A. LQG Performance Criterion and Integral Action

The dynamics of the cavity and measurement system can be subdivided as shown in Fig. 4 and comprises an electro-mechanical subsystem and an electro-optical subsystem (the optical cavity and homodyne detector).

FIG. 4: Block diagram of the plant.

The control objective is to minimize the cavity detuning Δ , which is not available for measurement. Instead, the measurement signal y is the output of the homodyne detector and to include Δ in the performance criterion, we need to relate Δ to z , the mean value of y . It can be seen from (7) that the transfer function of the optical cavity from Δ to z is a first-order low-pass filter with a corner frequency of $\kappa/2$. Physically, this arises from the well-known (see for example [24, 29] and the references therein) transfer function of the optical cavity from Δ to a phase shift, which is then measured by the homodyne detector. In the experimental system described herein $\kappa/2 \approx 10^5$ Hz, which is well beyond the frequency range of interest for the integral LQG controller. Hence we can consider z to be proportional to Δ under these conditions, and therefore minimizing variations in Δ can be regarded as being equivalent to minimizing variations in z .

The LQG performance criterion to be used for our problem is chosen to reflect the desired control system performance. That is, (i) to keep the cavity detuning Δ small (ideally zero), and (ii) to limit the control energy. However, these requirements are not sufficient to generate a suitable controller as the system is subject to a large initial DC offset and slowly varying disturbances. Our application requires the elimination of such effects. This can be achieved by using integral action and is the reason for our use of the integral LQG controller design method.

We include integral action by adding an additional term in the cost function which involves the integral of the quantity z . Moreover, we include the “integral state” as another variable of the system. The new variable $\int z dt$ is also fed to the Kalman filter, which when combined with an optimal state-feedback control law leads to an integral LQG optimal controller. This controller will then meet the desired performance requirements as described above; e.g., see [20].

Fig. 5 shows the integral LQG controller design configuration.

The overall system can be described in state-space form as follows:

$$\begin{aligned}\dot{\tilde{x}} &= \tilde{A}\tilde{x} + \tilde{B}w_1 + \tilde{B}u; \\ \tilde{y} &= \tilde{C}\tilde{x} + \begin{bmatrix} w_2 \\ w_3 \end{bmatrix};\end{aligned}\tag{9}$$

where

$$\tilde{x} = \begin{bmatrix} x \\ \int z d\tau \end{bmatrix} \quad \text{and} \quad \tilde{y} = \begin{bmatrix} y_1 \\ y_2 \end{bmatrix}.$$

FIG. 5: Integral LQG controller design configuration

Here the matrices $\tilde{A}, \tilde{B}, \tilde{C}$ are constructed from the matrices A, B, C as follows:

$$\tilde{A} = \begin{bmatrix} A & 0 \\ C & 0 \end{bmatrix}, \quad \tilde{B} = \begin{bmatrix} B \\ 0 \end{bmatrix}, \quad \text{and} \quad \tilde{C} = \begin{bmatrix} C & 0 \\ 0 & I \end{bmatrix}.$$

Section III outlines the technique used to determine A, B, C .

In equation (9), the quantity w_1 represents mechanical noise entering the system which is assumed to be Gaussian white noise with variance ϵ_1^2 . The quantity w_2 represents the sensor noise present in the system output y , which is assumed to be Gaussian white noise with variance ϵ_2^2 . The quantity w_3 is included to represent the sensor noise added to the quantity $\int z dt$. This is assumed to be Gaussian white noise with variance ϵ_3^2 and is included to fit into the standard framework for the LQG controller design. The parameters ϵ_1, ϵ_2 and ϵ_3 are treated as design parameters in the LQG controller design in Sec. IV B.

The integral LQG performance criterion can be written as:

$$\mathcal{J} = \lim_{T \rightarrow \infty} \mathbf{E} \left[\frac{1}{T} \int_0^T [x^T Q x + L(z)^T \bar{Q} L(z) + u^T R u] dt \right] \quad (10)$$

where

$$L(z) = \int_0^t z(\tau) d\tau.$$

We choose the matrices Q, R and $\bar{Q}$ such that

$$x^T Q x = |z|^2, \quad u^T R u = r|u|^2, \quad \text{and} \quad \bar{Q} = \bar{q},$$

where $r > 0$ and $\bar{q} > 0$ are also treated as design parameters.

The first term of the integrand in (10) ensures that the controlled variable z goes to zero, while the second term forces the integral of the controlled variable to go to zero. Also,

the third term serves to limit the control input magnitude. The expectation in (10) is with respect to the classical Gaussian noise processes described previously, and the assumed Gaussian initial conditions. Given our system as described by (9), the optimal LQG controller is given by (e.g., see [19])

$$u = -r^{-1}\tilde{B}^T X \hat{\tilde{x}} = F \hat{\tilde{x}}, \quad (11)$$

where X is the solution of the following matrix Riccati equation

$$0 = X\tilde{A} + \tilde{A}^T X + \tilde{Q} - r^{-1}X\tilde{B}^T\tilde{B}X, \quad (12)$$

and

$$\tilde{Q} = \tilde{C}^T \begin{bmatrix} 1 & 0 \\ 0 & \bar{q} \end{bmatrix} \tilde{C}.$$

Here $\hat{\tilde{x}}$ is an optimal estimate of the vector of plant variables $\tilde{x}$ obtained via a steady state Kalman filter which can be described by the state equations

$$\dot{\hat{\tilde{x}}} = \tilde{A}\hat{\tilde{x}} + \tilde{B}u + K[\tilde{y} - \tilde{C}\hat{\tilde{x}}]. \quad (13)$$

For the case of uncorrelated process and measurement noises, the steady state Kalman filter is obtained by choosing the gain matrix K in (13) as

$$K = P\tilde{C}^T V_2^{-1}, \quad (14)$$

where P is the solution of the matrix Riccati equation

$$0 = \tilde{A}P + P\tilde{A}^T + V_1 - P\tilde{C}^T V_2^{-1} \tilde{C}P. \quad (15)$$

Here

$$V_1 = \epsilon_1^2 \tilde{B}\tilde{B}^T = \mathbf{E}[w_1 w_1^T] \quad \text{and} \quad V_2 = \begin{bmatrix} \epsilon_2^2 & 0 \\ 0 & \epsilon_3^2 \end{bmatrix}$$

define the covariance of the process and measurement noises respectively.

B. Design Parameters

In designing the LQG controller, the parameters ϵ_1^2 (the mechanical noise variance), ϵ_2^2 (the sensor noise variance of y), ϵ_3^2 (the variance of the sensor noise added to $\int z$), r (the

control energy weighting in the LQG cost function) and $\bar{q}$ (the integral output weighting in the LQG cost function) were used as design parameters and were adjusted for good controller performance. This includes a requirement that the control system have suitable gain and phase margins and a reasonable controller bandwidth. The specific values used for the design are shown in Table I:

Design parameter	Value
ϵ_1	5×10^{-2}
ϵ_2	500
ϵ_3	3×10^{-4}
r	1×10^3
$\bar{q}$	1×10^6

TABLE I: Design Parameter Values

These parameter values led to a 15th order LQG controller which is reduced to a 6th order controller using a frequency-weighted balanced controller reduction approach. We reduce the order of the controller to decrease the computational burden (and hence time-delay) of the controller when it is discretized and implemented on a digital computer. The new lower order model for the controller is determined via a certain controller reduction technique which minimizes the weighted frequency response error between the original controller transfer function and the reduced controller transfer function; see [30]. This is illustrated in Fig. 6 which shows Bode plots of the full-order controller and the reduced order controller. Formally, the reduced order controller is constructed so that the quantity

$$\left\| \frac{P(s)C(s)}{(I + P(s)C(s))} (C(s) - C_r(s)) \right\|_{\infty} \quad (16)$$

is minimized. Here, $P(s) = \tilde{C}(sI - \tilde{A})^{-1}\tilde{B}$, is the plant transfer function matrix and $C(s) = F(sI - \tilde{A} + K\tilde{C} - \tilde{B}F)^{-1}K$ is the original full controller transfer function matrix. Also, $C_r(s)$ is the reduced dimension controller transfer function matrix. The notation $\|M(s)\|_{\infty}$ refers to the H^{∞} norm of a transfer function matrix $M(s)$ which is defined to be the maximum of $\sigma_{max}[M(i\omega)]$ over all frequencies $\omega \geq 0$. Here $\sigma_{max}[M(i\omega)]$ refers to the maximum singular value of the matrix $M(i\omega)$.

Note that this approach to controller reduction does not guarantee the stability of the closed loop system with the reduced controller. We check for closed loop stability separately after the controller reduction process.

FIG. 6: Full and reduced-order continuous LQG controller Bode plots.

The reduced controller is then discretized at a sampling rate of 50 kHz and the corresponding Bode plot of the discrete-time loop gain is shown in Fig. 7. This discretized controller provides good gain and phase margins of 16.2 dB and 63° respectively.

FIG. 7: Bode plot of loop gain L . The controller provides a gain margin of 16 dB and 63° phase margin.

V. EXPERIMENTAL RESULTS

The discrete controller is implemented on a dSpace DS1103 Power PC DSP Board. This board is fully programmable from a Simulink block diagram and possesses 16-bit resolution. The controller successfully stabilizes the frequency in the optical cavity, locking its resonance to that of the laser frequency, f_0 ; see [31]. This can be seen from the experimentally measured step response shown in Fig. 8. This step response was measured by applying a step disturbance of magnitude 0.1 V to the closed-loop system as shown in Figure 9. Here r is the step input signal and y is the resulting step response signal which was measured.

FIG. 8: Step Response of the closed-loop system to an input of 0.1 V.

FIG. 9: Setup used to measure the closed-loop step response

VI. CONCLUSION AND FUTURE WORK

In this paper, we have shown that a systematic modern control technique such as LQG integral control can be applied to a problem in experimental quantum optics which has previously been addressed using traditional approaches to controller design. From frequency response data gathered, we have successfully modeled the optical cavity system, and used an extended version of the LQG cost functional to formulate the specific requirements of the control problem. A controller was obtained and implemented which locks the resonant frequency of the cavity to that of the laser frequency.

To improve on the current system, one might consider using additional actuators such as a phase modulator situated within the cavity or an additional piezo actuator to control the driving laser. Additional sensors which could be considered include using a beam splitter and another homodyne detector to measure the other optical quadrature and an accelerometer or a capacitive sensor to provide additional measurements of the mechanical subsystem. In addition, it may be useful to control the effects of air turbulence within the cavity and an additional interferometric sensor could be included to measure the optical path length adjacent to the cavity. Such a measurement would be correlated to the air turbulence effects within the cavity. All of these additional actuators and sensors could be expected to improve the control system performance provided they were appropriately exploited using a systematic multivariable control system design methodology such as LQG control.

One important advantage of the LQG technique is that it can be extended in a straightforward way to multivariable control systems with multiple sensors and actuators. Moreover, the subspace approach to identification used to determine the plant is particularly suited to multivariable systems. It is our intention to further the current work by controlling the laser pump power using a similar scheme as the one used in this paper. This work is expected to pave the way for extremely stable lasers with fluctuations approaching the quantum noise limit and which could be potentially used in a wide range of applications in high precision metrology, see [32].
